16. Abstract  I. <u>ABSTRACT</u>  A supersonic tip speed single stage fan was modified with the intent of reducing multiple pure tone (MPT) or "buzz saw" noise. There were three modifications to the blades from the original design. The modifications to the blade resulted in an increase in cascade throat area causing the shock to start at a lower corrected fan speed. The acoustic results without acoustically absorbing liners showed substantial reduction in multiple pure tone levels. However, an increase in the blade passing frequency noise at takeoff fan speed accompanied the MPT reduction. The net result however, was a reduction in the maximum 1000-foot (304.8 m) altitude level flyover PNL.  For the case with acoustic treatment in the inlet outer wall, the takeoff noise increased relative to an acoustically treated baseline. This was largely due to the increased blade passing frequency noise which was not effectively reduced by the liner.

## I. SUMMARY

During the NASA/GE Quiet Engine Program, a supersonic tip speed fan, designated Fan "C", was constructed in a 36-inch (91.44 cm) diameter size (of linear scale of a full-size Fan "C"). As part of the Fan "C" test program, several blade modifications were made to determine if aerodynamic design changes could be affected which would reduce supersonic tip speed noise. The fan had 26 rotor blades and 60 outlet guide vanes (OGV). The basic fan was designed for a corrected tip speed of 1550 ft/sec (472.44 m/sec) at a bypass pressure ratio of 1.6.

The fan was tested with three blade modifications in addition to the basic design. Each modification was tested with and without acoustic treatment. Tables I and II below summarize the 1/3-octave sound pressure levels (SPL's) at the 100-foot (30.48 m) arc for the dominant multiple pure tones (MPT's), blade passing frequency (BPF), and second harmonic in the untreated and treated configurations. The acoustic results without acoustic treatment show a substantial reduction in multiple pure tone levels. However, an increase in blade passing frequency and second harmonic noise at take-off fan speed is also evident. The treated configurations (Table II) also show a decrease in the MPT's while the BPF and second harmonic increased.

Table III summarizes the front maximum level flyover PNL's for the treated and untreated configurations at approach and takeoff. The differences in PNL's are small relative to "Mod II" primarily due to the increase in BPF and the second harmonic. The treated "Mod VIII" configuration, however, contained 3.5 inches (8.89 cm) (19.4%) less acoustic treatment than the other configurations. This might account for some of the difference in noise for that modification.

## II. INTRODUCTION

The major objective of this program was to obtain a high tip speed blade design which would provide good performance and reduce the multiple pure tones associated with supersonic tip speeds.

It generally is accepted that fan or compressor noise can be categorized as:

- Blade passing frequency and harmonics
- Broadband
- Multiple pure tones

The latter are unique characteristics of rotor blades operating at supersonic tip relative mach numbers. A spectrum controlled by such tones is shown in Figure 1. This particular case is a result obtained on the original blade contour discussed in this report. The MPT's are, in fact, higher than the blade passing frequency (BPF) and its harmonics.

It is this type of noise, MPT's, which were the principal target in dictating the design modifications investigated in this study. The view taken of the generating mechanism of MPT's was that they are a result of the non-uniformity of the bow shock pattern which develops on the outer portion of a supersonic tip speed rotor blade. The pattern is made up of the individual shocks from each blade which are nonuniform in amplitude as well as nonuniformly spaced around the rotor. Resolution of this pattern into sinusoidal wave components results in the tones at integral multiples of one-per-rev as shown in Figure 1.

There is, at present, some controversy as to whether nonuniform spacing and/or amplitude are the most significant parameters in determining MPT noise signature. Furthermore, there are two principle methods by which shock pattern nonuniformities can be introduced: first, blade-to-blade geometric differences such as blade-to-blade spacing, individual blade stagger and camber, and blade radial dimensional variations; and second, circumferential nonuniform inflow conditions such as turbulence scale and amplitude.

However, one past test result which gave an indication of a method of noise reduction was that, as fan speed was increased beyond the take-off point, MPT levels appear to decrease (1). This speed range is generally associated with the swallowing of the shock which extends across neighboring blade passages. With this in mind, a change in the blade geometry was suggested which would put the shock in the swallowed position at takeoff and, thus, result in lower noise at this key noise measuring condition.

Although the design changes were expected to reduce take-off MPT noise, it was uncertain what the effect would be on blade passing frequency noise at takeoff, broadband, BPF noise at approach, and aerodynamic performance particularly at cruise (100% fan speed).

### III. VEHICLE DESCRIPTION

This scale model fan was designated as Fan "C" in the Quiet Engine Program and was approximately a half-scale (52.7%) of the full-size fan. A cross-sectional sketch of the fan vehicle is shown in Figure 2. The fan has 26 rotor blades and 60 outlet guide vanes with an axial spacing between blade rows of two rotor tip chords. The basic fan was designed to produce a pressure ratio of 1.6 at a corrected tip speed of 1550 ft/sec (472.44 m/sec).

For some of the testing, acoustic treatment was placed on the fan duct walls. Figure 2 shows the location of acoustic treatment. The treatment material consists of 1/2-inch (1.3 cm) open-celled polyurethane foam (Scott-felt) backed by a solid plate and covered with a perforated face sheet. The face sheet has a porosity of 22-1/2%. Scottfelt, in general, is not a flight-worthy material and tends to exhibit noise suppression characteristics which exceed flight qualified materials. However, since all four tests were conducted with the same type of suppression material, the results are comparable.

As shown in Figure 2, "Mod VIII" had 3.5 inches (8.89 cm) less inlet treatment than the other MOD's. The data of "Mod VIII" with treatment, therefore, should be interpreted with this in mind.

For the untreated configurations, the treatment was neutralized by covering it with an adhesive-backed foil tape.

Aerodynamic data were taken with arc rakes ahead of and behind the fan package. These rakes and other aerodynamic probes were removable so they would not interfere with acoustic testing.

#### IV. TEST PROGRAM AND DATA ANALYSIS

The test program was conducted at General Electric's Peebles test site. The vehicle was located on the scale model fan component test stand as shown in Figure 3. The fan was driven by a front drive shaft powered through a gearbox by a General Electric LM1500 gas turbine engine. The gearbox and the LM1500 are contained within acoustically absorbing housings to prevent any contamination of the measured noise.

Acoustic data were taken by microphones placed on a 100-foot (30.48 m) arc centered at the fan inlet centerline at a height of 15 feet (4.572 m). The microphones were placed at 10-degree intervals from 20 degrees from the inlet axis around to 160 degrees from the inlet axis. The field between the microphones and the vehicle is covered with asphalt.

Acoustic testing was restricted to steady winds of 5 mph (8.03 km/hr) and gusts of no more than 3 mph (4.82 Km/hr) above the maximum steady wind from any direction. In addition, data were not taken when the field was wet or covered with snow, the relative humidity was less than 30% or in excess of 90%, or temperatures less than 20° F (-6.6° C). Also, all instrumentation protruding into the flowpath was removed prior to acoustic testing.

Acoustic data were recorded on a 28-channel Sagamo recorder with appropriate amplifiers for simultaneously recording 26 channels of acoustic data on FM with flat response through 20 KHz at a tape speed of 60 in/sec (152.4 cm/sec).

Data were taken over a range of speeds from 50% to 100% of the design speed in most cases. For each data point a repeat point was also taken. The repeat point helps to establish the scatter which is an integral part of all testing that relies on the average of a time-unsteady signal.

All four blade designs were tested in the treated and untreated configuration. The untreated configuration was obtained by taping the treated areas with a metal-impregnated tape which has demonstrated "hard" acoustic properties.

The acoustic data were analyzed in two ways. Most of the analysis was in 1/3-octave bands. These were obtained using a filter set and a 32-second averaging time. All data were corrected to a standard day of 59° F (15° C) and 70% relative humidity. The other method of analysis was through narrow-band filtering in 20-Hz bandwidths. For these analyses a UA-6A Federal Scientific Ubiquitous spectrum analyzer and a high resolution digital averager were used with a 12.8-second averaging time. This method of analysis provides a more definitive look at the spectrum than does 1/3-octave analysis, particularly when pure tone content is under investigation.

Ample aerodynamic data were acquired to determine the flow, pressure ratio, and efficiency of the fan on each operating line tested.

Together, the acoustic and aerodynamic data establish the performance tradeoffs for a given noise decrease.

## V. TECHNICAL DISCUSSION

### A. DATA PRESENTATION

#### 1. Noise Scaling

The data presented have been scaled to reflect a full-scale fan design except where noted. The scale factor was .527 based on the full-scale fan which is 68.4 inches (173.736 cm) in diameter. The effect of adjusting the data to full-scale is to lower the frequency spectrum, since for a given tip speed a larger fan turns at a lower rotational speed than a smaller fan. For the case being considered, the scaling requires a downward shift of three 1/3-octave bands or one octave. In addition, adjustment for scale raises the level of noise by 10 times the logarithm of the ratio of the weight flow into the full-scale and the weight flow into the scale model.

By employing the scaling process, a more realistic evaluation of the extrapolation of the noise data to far distances from the fan can be obtained. This is true because of the difference in attenuation of various frequency noises in air. With the spectral components of noise in their proper bands, this attenuation is applied in a more realistic manner.

#### 2. Core Jet Noise

The test vehicle used here, of course, does not contain the core jet. In many instances, this noise has a "dampening effect" on the overall engine noise reduction brought about by a fan noise reduction, since the jet noise may make a measureable contribution to the PNL. For this reason, some of the data presented in this report contain an addition for the core jet noise of a full-scale engine.

The jet noise levels were predicted from a correlation of jet noise data based on the weight flow, area, and velocity of the jet<sup>(2)</sup>. For this case these parameters were:

Weight flow - 143 lbm/sec (64.92 kg/sec)

Area - 5.9 ft<sup>2</sup> (.5483 m<sup>2</sup>)

Velocity - 856 ft/sec (260.9088 m/sec)

for the take-off fan speed, and:

Weight flow - 85 lbm/sec (38.59 kg/sec)

Area - 5.9 ft<sup>2</sup> (.5483 m<sup>2</sup>)

Velocity - 406 ft/sec (123.7488 m/sec)

for the fan approach fan speed.

### 3. Flight Velocity Effects

There are two direct effects of aircraft flight velocity which alter the noise spectra. First, the velocity results in Doppler shifting of the spectrum. In the cases being considered here, a flight velocity of 275 ft/sec (83.82 m/sec) ( $M = .25$ ) was used. Where applicable Doppler shifting was included for level flyovers of the fan and core jet noise. The Doppler shift is made according to value of the Doppler factor - defined as  $1/(1 + M)$  where  $M$  is the component of flight Mach number in the direction from the airplane to the microphone. If when this factor is multiplied by the 1/3-octave center frequencies, the result is a frequency in a neighboring band, a shift is made. Thus, if the factor exceeds 1.12 or is less than .89, a 1/3-octave band shift is made - to a higher frequency when the factor is 1.12 (source moving toward the observer), and to a lower frequency when the factor is .89 (source moving away from the observer).

A second effect acts to reduce the jet noise. This is due to a reduction in the relative velocity between the jet and the surrounding air (ambient air). The test data, of course, are taken statically; thus, a correction is required. This correction is computed by using the jet noise predictions recommended in the SAE's Air 876 "Jet Noise Prediction." The static and flight spectra are predicted for the fan jet as suggested by Air 876.

The parameters used for the fan were:

Weight flow - 668 lbm/sec (303.272 kg/sec)  
Area -  $10.7 \text{ ft}^2 (.9944 \text{ m}^2)$   
Velocity - 886 ft/sec (270.0528 m/sec)

at take-off fan speed and:

Weight flow - 415 lbm/sec (188.41 kg/sec)  
Area -  $10.7 \text{ ft}^2 (.9944 \text{ m}^2)$   
Velocity - 530 ft/sec (161.544 m/sec)

at approach fan speed. The differences between the predicted spectra for static and flight conditions are then determined and subtracted from the test data to obtain a "corrected" to flight spectrum.

In addition the frequency range over which the relative velocity correction is applied is important. That is, the relative velocity correction can only be applied over the frequency range in which jet noise is dominant. The determination of this point is largely done by examining the test spectra and designating the frequency by noting the dip in noise level which generally denotes the jet region (usually below 400 Hz) and the fan dominant region (usually above 400 Hz). The resulting spectra are then smoothed between the two regions of the spectra which are dominated by fan and jet noise.

Together the alterations made to the basic data cited above provide a means for evaluation of the test results under more meaningful conditions than would be provided by the static scale model fan data alone.

#### B. AEROACOUSTIC DESIGN CONSIDERATIONS

In each case tested, the basic intent was to alter the shock structure so as to reduce the multiple pure tone (MPT) noise. Figure 4 shows an overlay of the four airfoils tested. These sections are all at a radius of 16.86 inches (42.82 cm).

The airfoil labeled "Mod II" was designed by "conventional" practices. That is, the design point (100% corrected fan speed) performance was a key criterion. Since performance of high speed blading is highly dependent on the bow shock position, the airfoil shape and cascade geometry are tailored to put the shock in a "swallowed" position which results in a minimum of shock losses. One of the acoustic characteristics of such a blade is a drop-off in noise level as thrust is increased past the take-off thrust (usually above 100% of take-off thrust, see Figure 30 "Mod II" data). With this in mind, it was reasoned that, if the design shock position was obtained at takeoff, the take-off noise would be lower. The "Mod III" blade represents this design. From the performance point of view, this design change was expected to decrease design point efficiency.

The next blade shape selected was actually contrived from the "Mod III" by closing the blade (i.e., restaggering the blade so as to improve the incidence/blade angle match). It was hypothesized that this would help to increase the design point performance without affecting the noise output. One of the side effects of this change was that at a given corrected speed the flow and pressure ratio were lower than they were for "Mods II and III." This requires some correction to the acoustic data to put the absolute noise level data on a comparable basis. This was done by making several comparisons at constant thrust.

The last blade selected for testing, designated "Mod VIII," was an attempt to bring about an increase in design point efficiency while maintaining the acoustic characteristics of the "Mod III" blade design. Figure 5 shows the "Mod II, VII, and VIII" blades. The "Mod VIII" blade was thickened at the tip in order to change the aerodynamic characteristics by weakening the secondary shock in the cascade. Also, in order to maintain the same general performance characteristics, it was necessary to decrease the tip slope.

Figure 6 shows the two flowpaths for "Mod II" and "Mod VIII." The flow-per-unit-area was slightly higher for "Mod VIII" ( $40.26 \text{ lb}/\text{ft}^2$ ,  $196.52 \text{ kg}/\text{sq m}$ ) than "Mod II" at speeds below the design speed. Again, this was "corrected" in looking at some acoustic results by comparing the data on an equal thrust basis.

#### C. UNTREATED NACELLE ACOUSTIC DATA

Each of the fans was run without acoustic treatment. This section contains the acoustic data for a full-scale fan tested statically and for

take-off and approach conditions in level flight. In order to keep a constant baseline each set of data is first presented relative to "Mod II." Then "Mod II" and "Mod VIII" are presented in absolute terms.

Figures 7-15 contain static data scaled to full-scale at take-off (90%) fan speed. The PNL difference between "Mod II" and the other blades, Figure 7, on a 200-foot (60.96-m) sideline shows "Mod III" blades with a 2.5 PNdB reduction from 50 through 90 degrees. However, the most significant changes can be seen in the 70-degree spectra (Figures 8 through 11). The modified blades all exhibit a significant drop in the 250 to 800 Hz range and an increase in the blade passing frequency at 2000 Hz. The "Mod VIII" blade also shows an increase in higher frequency noise. Figures 9-11 are narrowband comparisons of each blade to "Mod II." The lower frequency reduction is due to decrease MPT content. Increases in the blade passing frequency (BPF) and second harmonic are evident in each case.

For this unsuppressed case, the 120-degree spectra (Figure 12) also exhibit a low frequency noise decrease. This, however, is not reduction in rear-radiated noise but reduction in MPT's which radiate around from the front.

As a point of reference, Figures 13 through 15 show the absolute noise levels from "Mod II" and "Mod VIII." The 70-degree spectra, Figure 14, clearly show that the spectrum has changed from MPT dominant for "Mod II" to BPF dominant for "Mod VIII."

At 84% speed, Figures 16 through 18, the modified blades continue to show lower PNL. It should be noted also that the "Mod VIII" blade shows a rear noise reduction. Examination of the 110-degree spectra, Figure 18, shows the PNL reduction to be due to a decrease in multiple pure tones and to a reduction in BPF.

As speed is decreased further to 72%, Figures 19 and 20, the picture changes, and the modified blades are now slightly increasing noise. The 72% speed is the speed at which the rotor tip speed is just sonic. At approach power (57.5% speed), the trend toward increased noise is also evident with the modified blades. Figure 21 shows "Mod VIII's" noise to have increased relative to "Mod II" - about 4 PNdB at 50 degrees. Spectral comparisons, Figures 22 and 23, show the increase to be wide spread for "Mod VIII," while "Mods III and VII" show some decreases.

At rear angles, Figures 24 and 25, the "Mod VIII" increase also appears. On an absolute basis, Figures 26-28 show "Mod VIII" and "Mod II." At 70 degrees "Mod VIII's" increase is largely above the BPF, particularly at frequencies above the second harmonic (3150 Hz band).

As was noted in Section V-B, the blade modifications made to affect the shock pattern, and thus the MPT generation, resulted in changes in flow and pressure ratio at a given speed. In an attempt to smooth out these differences, Figures 29-32 contain 200-foot (60.96-m) sideline PNL data versus percent thrust. In general, the comparisons result in the same conclusions as seen in comparisons at constant corrected fan speed. Figure 29 shows "Mod VIII" decreasing take-off noise by one PNdB and increasing approach noise by one PNdB at the front maximum. Figures 13 for take-off and 26 for approach speed show approximately the same result.

The absolute level of "Mods II and VIII" at the front maximum is shown in Figure 30. The characteristic drop in level at high speed is clearly seen. For "Mod VIII" this drop starts above 90% of take-off thrust; while, for "Mod II," the drop does not start until above 100% thrust. This decrease in the drop-off thrust level was one of the desired test results.

Figure 31 contains delta PNL data at the rear maximum on a 200-foot (60.96-m) sideline versus thrust. At low thrust none of the blades shows a noise reduction. At higher thrusts only "Mod VIII" shows no increase in level. On an absolute basis, Figure 32 shows a monotonic increase with thrust for "Mods II and VIII."

Figures 33-40 contain projections of the static noise at takeoff and approach to flight conditions at altitudes of 1000 and 370 feet (304.8 and 112.776 m) respectively. The flight Mach number was 0.25. Core jet noise has been predicted and added to the fan noise to provide a more realistic flight projection (see Section IV).

The take-off data, Figures 33-36, show a slightly greater noise reduction on a PNL basis than was indicated at 200 feet (60.96 m) (Figures 7-15). Tone correcting the data, Figure 34, however, reduces the reduction due to the modifications, largely because of the increase EPN levels. Figures 35 and 36 contain absolute level data on "Mods II and VIII." The PNL reduction at the maximum angle is 3 PNdB, but the PNLT reduction is only 1.1 PNdB. On an EPNL basis, this leaves only a 0.4 EPNdB reduction.

At approach thrust, Figures 37-40, the adverse effect of the modifications seen at 200 feet (60.96 m) has been reduced. This is largely due to the increased distance which decreases the importance of the high frequency noise increase as seen in Figure 27. Tone correcting the data, Figure 38, has only a small effect; however, the overall result is an increase of 0.8 EPNdB between "Mods II and VIII" (Figures 39 and 40).

#### D. TREATED NACELLE ACOUSTIC DATA

A description of the treated nacelle is contained in Section III. Figures 41-49 contain take-off data for the modified blades. The 200-foot (60.96-m) sideline PNL shows an increase for all three blades at 70 degrees with "Mod VIII" 2.6 PNdB greater than "Mod II" as shown in Figures 42-44. In general, the treatment decreases the MPT activity of all the blades. For "Mod III" the MPT's decrease still further, but the BPF and second harmonic have increased. "Mod III" also shows a decrease in background level at high frequencies. "Mod VIII" also shows decreased MPT levels (Figure 44), but the higher frequency background noise is higher in level than "Mod II" as are the BPF and second harmonic.

The relative 1/3-octave spectral levels (Figures 45 and 46, at 70 and 120 degrees, respectively) show the effect of the MPT decrease and BPF and second harmonic increases. A decrease of 12.5 dB is obtained at 400 Hz, while an increase of about 7.5 dB occurs at the BPF for each modified blade at 80 degrees. At 120 degrees the "Mod III" blade shows the smallest change relative to "Mod II."

Absolute level data for "Mod VIII" and "Mod II" are shown in Figures 47-49. The BPF level at 70 degrees is 99 dB, while at 120 degrees the level is 93.5 dB. This differential, and the fact that the vehicle has a large aft suppressor, indicates that the rear noise tone increases are due to inlet-radiated noise reaching the rear quadrant.

In the treated configuration, "Mod VIII" appears to be louder than "Mod II." Some of the differences quoted would be reduced, however, if the inlets had equivalent acoustic treatment (see Figure 2). Equivalent inlet treatments might, therefore, reduce the front quadrant differences between "Mod II" and "Mod VIII" and possibly eliminate the aft quadrant differences at takeoff (Figure 47). The difference in inlet noise might be 1.0 to 2.0 PNdB if a linear relationship is assumed between suppression and treatment length.

At 84% speed, Figures 50 and 51, the modified blades show a slight decrease in front end noise except for "Mod VIII," where the front maximum angle increased by about 4 PNdB relative to "Mod II." At 84% speed, the rotor tip speed is still supersonic, and the BPF has increased with the reduction of MPT's. This point is illustrated in Figure 52, where the BPF level shows an increase of 12 dB for "Mod VIII" relative to "Mod II."

As speed is decreased further to 72%, Figures 53 and 54, all of the modified blades are showing noise increases relative to "Mod II" at all angles. At 72% speed, the rotor tip speed is just sonic. At approach power (57.5% speed) the trend toward increased noise is also evident with the modified blades. Figure 55 shows "Mod VIII's" noise to have increased about 6 PNdB at 50 degrees relative to "Mod II" and about 5 PNdB at 130 degrees. Figures 56 and 57 show spectral comparisons for the front and rear maximum angles. The increase for "Mod VIII" is wide spread, while "Mods III and VII" show some decrease in noise throughout the frequency range. At 130 degrees the most significant increase is at the second harmonic - 8 dB - with lesser increases at the BPF and frequencies above the second harmonic.

On an absolute basis, Figures 58-60 show the PNL distribution and frequency spectra for the front and rear maximum for "Mods II and VIII." At the front maximum angle, "Mod VIII" shows an increase of 5.5 PNdB and about 4.5 PNdB for the rear maximum.

Figures 61-64 show the 200-foot (60.96-m) sideline maximum PNL variations with percent thrust for the fully treated modifications. In general, the comparison results in the same conclusion as with the data compared at constant corrected fan speed. Figure 61 shows "Mod VIII" increasing about 2 PNdB at take-off and about 4 PNdB at approach thrust. For takeoff, Figure 47 shows approximately the same result. At approach, Figure 58 shows "Mod VIII" to have increased by 5.5 PNdB, which is slightly higher than shown on Figure 62. Figure 61 shows that, at a lower thrust, the delta PNL increases to about 4.0 PNdB relative to "Mod II."

A comparison of the absolute levels for the front maximum is shown in Figure 62. The slopes of the curves indicate that both "Mod II and VIII" increase in noise at high thrust levels, but at a slower rate than at thrust levels below 85%. "Mod II" levels off at about take-off thrust, while "Mod VIII" decreases slightly. Although the characteristic drop in level at high thrust is not as evident for the treated configuration, the absolute levels are lower.

Figure 63 contains the delta PNL data for the rear maximum on a 200-foot (60.96-m) sideline versus percent of take-off thrust. Throughout the thrust range, only "Mod VII" shows a noise reduction relative to "Mod II." On an absolute basis, Figure 64 shows a monotonic increase with thrust for "Mods II and VIII."

Figures 65-72 contain projections of the static noise at takeoff and approach to flight conditions for the treated inlet. Altitudes of 1000 feet (304.8 m) and 370 feet (112.776 m) were used for takeoff and approach, respectively. The same procedure was used to represent level flyovers for the treated inlet as for the untreated inlet. That is, a core jet noise was added to the fan for more realistic flight projection. The flight Mach number was 0.25.

At takeoff, Figures 65-68, the delta PNL increase for "Mod VIII" relative to "Mod II" is approximately the same as that presented for the 200-foot (60.96-m) sideline (Figures 45-49). Tone correcting the data, Figure 66, however, shows an increase due to the modifications, primarily because of the increase in BPF levels. Figures 67 and 68 show absolute level data for "Mod II and VIII." The PNL increase at the maximum angle is about 2 PNdB, but the PNLT increase is about 2.8 PNdB. On an EPNL basis this represents an increase of 1.8 EPNdB, most of which is attributed to BPF.

At approach thrust, Figures 69-72, the PNL distribution is very similar to that of the 200-foot (60.96-m) sideline (Figure 58). Tone correcting the treated inlet data at approach, Figure 70, has the effect of increasing the noise levels about 1 to 2 PNdB throughout the arc, which results in an increase of 3.6 EPNdB between "Mods II and VIII" (Figures 71 and 72).

#### E. AERODYNAMIC PERFORMANCE DATA

For each of the blades, the performance map was determined by using a set of fixed nozzles with various areas. The performance maps are presented in Figures 73 and 74. The "Mod III," "Mod VII," and "Mod VIII" maps are superimposed on the basic configuration, "Mod II." The solid lines represent the "Mod II" performance while the symbols are for the modified blades. Figure 73 shows that "Mod III" blades pass higher flow up to 90% speed; at higher speeds, "Mod III" passes less flow. The smallest nozzle area used on "Mod III" produced an unstalled pressure ratio of 1.775. The nominal area,  $396 \text{ in}^2$  ( $2554.2 \text{ cm}^2$ ), exhaust nozzle produced the design pressure ratio of 1.6 at 100% corrected fan speed.

Up to 90% speed, Figure 75, "Mod VIII" passes less flow than "Mod II;" at higher speeds, "Mod VIII" passes more flow. The smallest nozzle used on "Mod VIII" produced an unstalled pressure ratio of 1.7 at 100% corrected fan speed. "Mod VIII" had a smaller annulus area and, therefore, passed less flow at the design speed. However, the specific flow ( $\text{lb}_m/\text{ft}^2$ ) ( $\text{kg}/\text{m}^2$ ) of the two fans is comparable.

Figures 76, 77, and 78 show the efficiency trend with corrected fan speed for each nozzle. With the nominal nozzle, the "Mod III" blade is about 2% better than "Mod II" at low speed and equivalent at takeoff, but drops appreciably at the design point. "Mod VII" has high efficiency at low speed but drops off rapidly at high speeds. At low speeds, "Mod VIII" efficiency is approximately equal to "Mod II" up to take-off speed. At design speed, "Mod VIII" is about 3% higher in efficiency than "Mod II."

It must be noted that the relatively short span of these blades results in a somewhat lower absolute efficiency level than a lower-radius-ratio fan. This is due to the high Mach number over the hub wall which locally reduces efficiency. However, on a comparative basis, these results are significant.

#### F. CONCLUDING REMARKS

Thus an airfoil design has been developed which results in a much lower level of MPT's without any sacrifice in fan cruise performance. In aerodynamic terms, a smaller precompression (less flow deceleration) is done in the forward part of the cascade than in a conventional blade in order to prevent the shock structure from escaping forward of the cascade. Also, the aft portion of the airfoils is shaped so as to provide a smooth deceleration and prevent the development of a strong passage shock wave. The effect acoustically is reduced MPT's, but an increase in the blade passing frequency. Although, the modified blade has a higher BPF, the total acoustic energy generated in the MPT's and BPF is less for the modified blades than the conventionally designed blade. The increased BPF level, however, will require that care be taken to place the BPF in a less annoying frequency band and/or tuned acoustic liners specifically for this increased noise.

VI. CONCLUSIONS

1. A change in the basic blade airfoil design criteria can act to reduce multiple pure tone (buzz saw) noise in supersonic tip speed fans.
2. Future design changes aimed at reducing multiple pure tones must acknowledge the possibility that the blade passing frequency will increase.

VII. NOMENCLATURE

BPF	Blade Passing Frequency
dB	Decibel
EPNL	Effective Perceived Noise Level
$F_n$	Engine Net Corrected Thrust
Hz	Hertz (Cycles per Second)
$M_o$	Aircraft Mach Number
Max	Maximum
Min	Minimum
MOD	Modification
$N/\sqrt{\theta}$	Fan Rotational Speed, Corrected to Standard Day
OGV	Outlet Guide Vane
$P_{T23}/P_{T2}$	Ratio of Fan Bypass Exit Total Pressure to Fan Inlet Total Pressure
PNdB	Perceived Noise Decibel
PNL	Perceived Noise Level; a Calculated Annoyance Weighted Sound Level
PNLT	Tone Corrected Perceived Noise Level
PWL	Sound Power Level, Re $10^{-13}$ Watts
QEP	Quiet Engine Program
SLS	Sea Level Static
SPL	Sound Pressure Level, Re 0.0002 Dynes/cm <sup>2</sup>
$w\sqrt{\theta}/\delta$	Bypass Airflow, Corrected to Standard Day, lbm/sec (kg/sec)

## VIII. APPENDIX - ONE-THIRD OCTAVE DATA

This appendix contains 1/3-octave scale model data corrected to 70% relative humidity on a 59° F (15° C) day. Each table consists of at least 24 bands of data at angles from 20 degrees to 160 degrees in 10-degree increments referenced to the inlet centerline.

The data presented are on 100-foot (30.48-m) arc and 200-foot (60.96 m) sideline for approach (57.5%) speed, take-off (90%) speed, 72% and 84% speeds. The 100-foot (30.48-m) arc is scale model data and the 200-foot (60.96-m) sideline data are full-scale. Data for all four blades in the treated and untreated configuration are included. All data are for the nominal fan nozzle.
